

KEY INSIGHTS

- The potential for direct emissions reductions varies across sectors, and **strategies vary within each sector depending on technology costs and availability.**
- In general, the **buildings, industry, and fuels sectors achieve lower percentage reductions than the power and transport sectors**, reflecting their higher marginal abatement costs.
- Electrification and low-carbon fuels can substitute for conventional fuels to reduce emissions, but the **marginal costs can rise steeply for some end-uses.** This leads to carbon dioxide removal use to offset fossil fuel emissions, which can lower costs relative to direct reductions for some end-uses.

This brief is based on the report "[LCRI Net-Zero 2050: Sensitivity Analysis and Updated Scenarios](#)" published on [epri.com](#)

Sectoral CO₂ Reductions for Economy-Wide Decarbonization

by Geoff Blanford and John Bistline

Analysis evaluates technology strategies for achieving economy-wide net-zero CO₂ emissions in the U.S. by 2050.

Many companies, states, and countries are setting net-zero emissions goals; however, there are many uncertainties related to potential pathways and technology trade-offs to reach these targets. This analysis uses EPRI's [REGEN model](#) to investigate a range of technology sensitivities and recent developments, including evolving policy incentives and emerging trends in [data center electricity use](#).

The [analysis](#) includes scenarios related to:

- Technology availability and cost assumptions for advanced nuclear, electrolysis, carbon capture and storage, and bioenergy
- Fuel price uncertainty
- Limited flexibility in how far individual sectors and regions are required to reduce direct emissions under an economy-wide target
- U.S. [Inflation Reduction Act](#) (IRA) incentives

More detail on scenario and analysis assumptions can be found [here](#).

Achieving economy-wide net-zero goals requires deployment of low-carbon technologies across electric and non-electric sectors, including industry, fuels, buildings, and transportation. The **potential for direct emissions reductions varies across sectors**, and optimal strategies vary within each sector depending on technology costs and availability (Fig. 1).

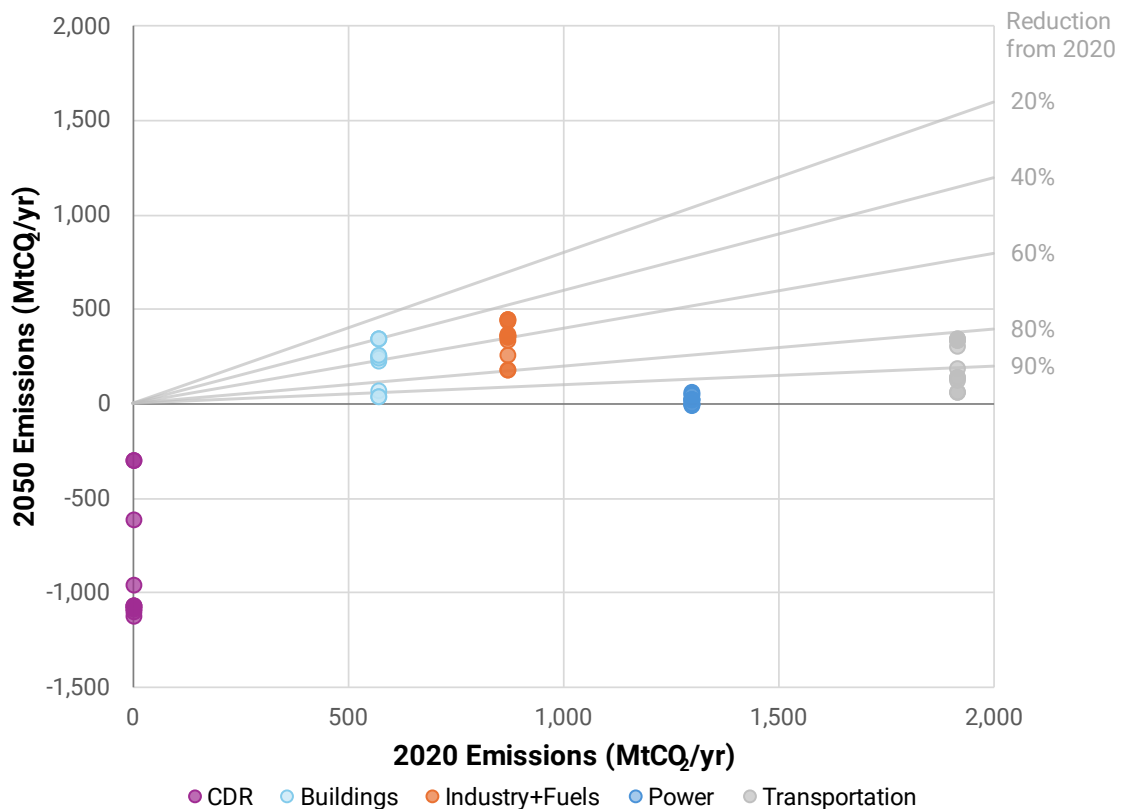

Figure 1. Economy-wide net CO₂ emissions by sector. See the [report table](#) for scenario definitions. Data points indicate net-zero scenarios. Diagonal lines indicate percentage reductions in 2050 relative to 2020 at the sector level. CDR = CO₂ removal.

- **In most net-zero scenarios, net power sector emissions are near-zero by 2050**, though some positive emissions remain for infrequently used [balancing resources](#).
- **In the non-electric sectors, direct emissions reductions in net-zero scenarios span a broader range.** In general, the buildings, industry, and fuels sectors achieve lower percentage reductions than the power and transportation sectors, reflecting their higher marginal abatement costs.

Electrification and low-carbon fuels can substitute for conventional fuels to reduce emissions, but the marginal costs can rise steeply for some end-uses, such as space heating in cold climates, high-temperature industrial processes, and transportation segments such as aviation. [Carbon dioxide removal](#) (CDR) from bioenergy with carbon capture and storage (CCS), direct air capture (DAC), and natural

processes such as afforestation can provide [cost-effective options to offset emissions](#) that would be expensive to reduce directly.

In general, the model identifies the least-cost combination of direct reductions and deployment of CDR technologies to meet the target balance between positive and negative emissions. The range of scenarios in this analysis demonstrates how this **balance can depend on uncertain technology and policy variables**. For instance, when CCS is unavailable and the scale of CDR is limited to ~300 MtCO₂ from [land-based offsets](#), direct positive emissions must be eliminated wherever possible. In these scenarios, positive emissions are reduced to around 95% of 2005 levels, but [marginal costs](#) of achieving the net-zero target approach \$1,000/tCO₂.

Fig. 2 shows direct sectoral emissions in the context of reductions relative to 2020 across scenarios. Most direct emissions in buildings,

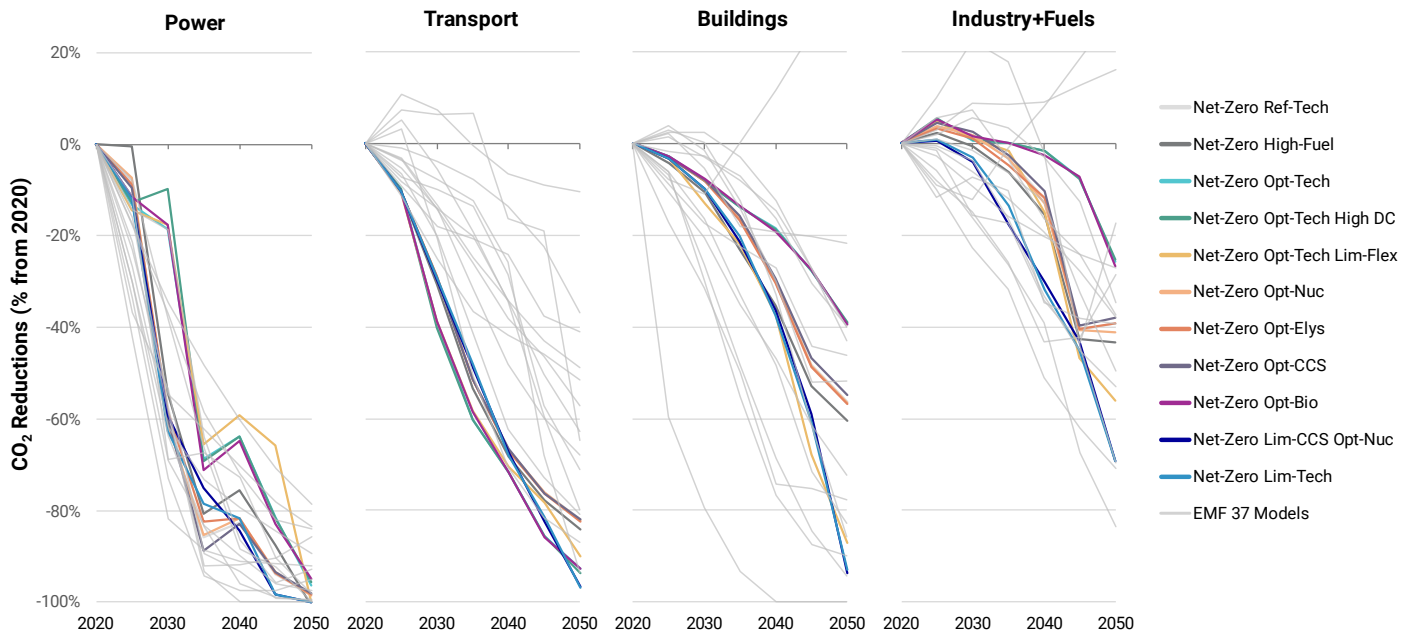

Figure 2. Sectoral CO₂ reductions for U.S. economy-wide net-zero CO₂ by 2050 scenarios. Panels indicate CO₂ reductions relative to 2020 levels for each sector. Scenarios from the LCRI Net-Zero 2050 analysis are compared with [Energy Modeling Forum 37](#) results.

industry, and fuels sectors are related to [natural gas use](#), which has higher substitution costs with electrification and low-carbon fuels than petroleum-based liquid fuels in the transportation sector. Power sector emissions are near-zero in all net-zero cases, although not absolutely zero, as a small amount of gas use remains as a [balancing option](#) for variable renewable generation. The **transportation sector exhibits deep reductions in the reference scenario due to electrification** of most on-road segments driven by favorable economics with cost and performance improvements of battery electric vehicles.

These findings are consistent with the emerging literature on reaching net-zero emissions in the U.S. See for example [Bistline, et al. \(2024\)](#), [Browning, et al. \(2023\)](#), and LCRI’s [model intercomparison](#) of net-

zero studies. For instance, Fig. 2 compares sectoral emissions reductions with values from the Energy Modeling Forum (EMF) 37 study of “[Deep Decarbonization & High Electrification Scenarios for North America](#).” These comparisons indicate broad alignment with the scenarios in this analysis, albeit with cross-model variation in trends.

For many scenarios, EPRI’s analysis generally has lower CDR use and greater direct reductions for many sectors. Net-zero scenarios in REGEN include greater transportation CO₂ reductions than most EMF 37 models due to electrification and low-carbon fuel substitution. Differences are models reflect alternate technological assumptions (e.g., cost, availability), service demand assumptions, as well as deployment constraints and equipment turnover.
